ABSTRACT

The Katzman Automatic Imaging Telescope (KAIT) at Lick Observatory observed GRB 021211 starting 105 s after the burst, among the earliest observations of an optical afterglow to date. Our well-sampled light curve, consisting of 18 points in the first 10 min and a total of 28 useful observations in the first 2.5 hr after the GRB, directly shows for the first time a break at $t \approx 10$ min. The light curve can be represented as a sum of two components with power-law decay indices of -1.82 ± 0.02 and -0.82 ± 0.11. We hypothesize that the data before the break were dominated by emission from the reverse shock, as was previously suggested for GRB 990123. Our data suggest that either GRB 021211 underwent a dramatic color change at early times, or there are small-scale variations superimposed on the power-law decay of the reverse-shock emission. The faintness of GRB 021211, coupled with the fast decline typical of optical afterglows, suggests that some of the "dark bursts" were not detected because optical observations commenced too late after the GRB.

Subject headings: gamma rays: bursts

1. INTRODUCTION

The majority of gamma-ray burst (GRB) optical afterglow (OA) observations have been obtained several hours after the bursts, owing mainly to the delay in getting X-ray images and/or the difficulties in localizing the GRBs in real time. Out of the ~ 40 detected GRB OAs, only GRB 990123 (Akerlof et al. 1999), GRB 021004 (Fox 2002), and GRB 021211 (Fox & Price 2002) were successfully detected within 10 min after the initial burst of gamma rays.

In this *Letter*, we report on early-time optical observations of GRB 021211 with the Katzman Automatic Imaging Telescope (KAIT). KAIT is a 0.76-m robotic telescope at Lick Observatory that is dedicated to searching for and observing supernovae and monitoring other celestial events. It is equipped with an Apogee AP7 back-illuminated CCD camera having a resolution of $0\farcs8$ pixel^{-1} and a total field of view of $\sim 6\farcm8 \times 6\farcm8$. More information on KAIT can be found in Li et al. (2000) and Filippenko et al. (2001), and the KAIT GRB alert system is described in detail elsewhere (Li et al. 2003).

2. OBSERVATIONS

On 2002 December 11, 11:18:34.03 UT (defined as $t = 0$ in this paper), a bright GRB triggered the HETE-2 satellite (Crew et al. 2002). The gamma-ray light curve shows a single peak lasting ~ 2.5 s. The flight localization of the GRB was reported in a GRB Coordinates Network (GCN; Barthelmy et al. 1994) notice at $t = 22$ s.

The KAIT GRB alert program received the GCN notice with the position of GRB 021211 at $t = 32$ s. At the time, KAIT was conducting followup observations of one of its supernova discoveries, SN 2002he, and was 478 s into a 600-s B-band exposure (a rare, long exposure; most are only 20 s). KAIT performed some checks to ensure that the GRB was observable, stopped the autoguider, rotated the filter wheel so that no filter was in the way of the light path, and began to slew across much of the sky to the GRB position at $t = 49$ s. Currently, KAIT cannot stop an exposure in progress, so the shutter remained open during the long move to the opposite side of the sky, fortunately imaging only the dark, slowly rotating dome. The dome slit was centered on the GRB position at $t = 108$ s, with 48 s left in the ongoing exposure. The effective start time for the GRB exposure is $t = 105$ s.[1] This exposure, with the SN 2002he field and the GRB 021211 field superimposed, is shown in Figure 1a.

KAIT then began its pre-programmed sequence of GRB images. It started with a 10-s exposure at $t = 171$ s (Fig. 1b), continued with a 40-s exposure, five 3×20 s grid images (for a total of 15 individual exposures of the GRB), two 60-s exposures, one 120-s guided exposure, one 300-s guided exposure, and four 120-s guided exposures that together make a mosaic covering $12\farcm7 \times 12\farcm7$ around the GRB position. One of the 3×20 s grid images is shown in Figure 1c. Such grid images, in which the telescope is moved by $36''$ in right ascension between consecutive exposures, save two readout times (10 s each).

[1]We have conducted tests to repeat the same pointing procedure, and concluded that the dome cleared the telescope 3 s earlier than centering on the GRB position.

KAIT received three more GCN notices on GRB 021211 in the next 3 hr, and repeated the same sequence each time. The notices arrived at 11:53:30 UT, 12:25:24 UT, and 13:29:33 UT, which correspond to 2096 s, 4010 s, and 7859 s after the burst, respectively. KAIT was conducting the regular supernova search (20-s exposures) when these notices arrived, and was able to start the respective GRB exposure 35 s, 23 s, and 45 s after receiving the GCN notice. A total of 61 images (including the one superimposed on the field of SN 2002he) were obtained, with 101 individual exposures of GRB 021211. Unfortunately, there were passing clouds during the night, and the short exposures in the last three sequences do not go sufficiently deep to detect the GRB.

Since our observations were obtained without filters, it is important to transform the measured magnitudes to a standard photometric system, so that comparisons with observations obtained elsewhere can be made. Details of transforming the unfiltered magnitudes to the standard Cousins R are described by Li et al. (2003); see also Riess et al. (1999). These papers demonstrate that when the unfiltered observations are treated as though they were obtained with a broadband filter, and color terms are applied to correct for the difference in the throughput curves, the observed unfiltered magnitude can be transferred to a standard passband with a precision of $\sim 5\%$. The color terms are determined by observing Landolt standard stars in $BVRI$ and without filters during photometric nights; a value of 0.27 ± 0.05 mag is found for transforming KAIT unfiltered magnitudes to Cousins R. Knowledge of the $(V-R)$ color of GRB 021211 is also needed for the transformation, and we assume $(V-R) = 0.2$ mag, similar to that of GRB 990123 (Fruchter et al. 1999). A different choice of $(V-R)$ for GRB 021211 will make our measurements systematically brighter or fainter. For example, if $(V-R) = 0.5$ mag were used, our measurements would need to be made 0.08 mag brighter.

We used the PSF-fitting technique to reduce our data. For the grid images, the PSF for an individual exposure is constructed by using stars in that exposure only. Absolute photometric calibration of the GRB 021211 field is provided by Henden (2002). Our final photometry in the R band is listed in Table 1. In total, 28 useful data points were measured from the observations, 18 of which were obtained within 10 min after the burst.

3. RESULTS

Figure 2 displays the early-time light curve of GRB 021211 from the KAIT observations. We assume no host galaxy reddening to GRB 021211, and adopt a Galactic extinction of $A_R = 0.065$ mag (Schlegel, Finkbeiner, & Davis 1998) for the figure. The data show a steep initial decline, well fit by a power-law decay, with indexes measured as -1.56 ± 0.02 for

the first 4 points, and -1.58 ± 0.02 for the first 12 points. An apparent break is seen at $t \approx 0.1$–0.2 hr, when the GRB switches to a slower power-law decay, with indexes measured as -1.01 ± 0.05 from the last 7 points and -0.94 ± 0.06 from the last 6 points. The power-law indexes reported here are consistent with, but supersede, those measured by Chornock et al. (2002) from the preliminary reduction of the KAIT data (Li et al. 2002).

To better describe the temporal evolution of the OA of GRB 021211, we fit the data with the sum of two power-law decays:

$$F_\nu = 0.5\, F_{\nu,b}\, [(t/t_b)^{-\alpha_1} + (t/t_b)^{-\alpha_2}], \tag{1}$$

where t_b is the time of the break, and $F_{\nu,b}$ is the flux at t_b. We obtained the following values for the parameters using a χ^2-minimizing procedure: $\alpha_1 = 1.82 \pm 0.02$, $\alpha_2 = 0.82 \pm 0.11$, and $t_b = 0.18 \pm 0.03$ hr (= 10.2 min). These parameters are consistent with those found by Fox et al. (2003) with independent later-epoch data. The solid line in the upper panel of Figure 2 shows this fit, while the lower panel shows the residuals of the fit. The reduced χ^2 of the fit is 3.34 for 25 degrees of freedom, indicating that eq. (1) is not a good model for the data at the 8σ confidence level,[2] and suggest that the short timescale variations in the residuals seen in the lower panel of Figure 2 (and especially before t_b) are real features.

If we exclude the first data point, the model fit to eq. (1) becomes acceptable (reduced $\chi^2 = 1.03$). However, we have no *a priori* reason to suspect the first data point is anomalous. For the first point to be consistent with the simple double-power-law model, (1) the flux-weighted mean exposure time would have to be 135.0 s, which is 4.5 s after the midpoint of the exposure, (2) the photometry error bar would have to be increased to 0.08 mag, or (3) the GRB would have to have been 0.11 mag brighter than our measurement. The first option requires the GRB to be brightening during the exposure, and is ruled out as the earlier RAPTOR image (Wozniak et al. 2002) shows the GRB already declining. The second option is also not viable, because the OA is bright and well-detected. The third option is possible if the color of the GRB underwent a dramatic change at early times — e.g., the $V - R$ color was 0.6 mag during the first exposure, and became bluer to 0.2 mag (adopted in the photometric reductions) starting from the second exposure.

[2]We have additionally tried to fit the data with smoothly broken power-law models of varying sharpness, but these did not change the results significantly.

4. DISCUSSION

The OA of GRB 021211 was first identified by Fox & Price (2002) in images taken with the Palomar 1.2-m Oschin Schmidt telescope, beginning about 20 min after the burst. It was caught at early times by two robotic telescopes besides KAIT. The RAPTOR team obtained one image of GRB 021211 at $t = 65$ s (Wozniak et al. 2002), the second-earliest detection ever of an afterglow (only GRB 990123 was detected earlier at $t = 23$ s; Akerlof et al. 1999), and Super-LOTIS observations began at $t = 143$ s (Park, Williams, & Barthelmy 2002). Attempts to detect the afterglow of GRB 021211 in other energy bands all failed: these include the prompt GeV/TeV emission by Milagro (McEnery 2002), the sub-mm search by Hoge et al. (2002) on Dec. 12, and the radio searches by Berger & Frail (2002) on Dec. 12 and by Rol & Strom (2002) on Dec. 12 and 17. Late-time spectroscopy at the location of GRB 021211 shows underlying emission consistent with a host galaxy at probable redshift 1.006 (Vreeswijk et al. 2003).

GRB 021211 is only the second GRB with prompt optical data, so it is of interest to compare its light curve with that of GRB 990123 (Akerlof et al. 1999). In Figure 3, the data for GRB 990123 were collected from various sources as listed in Fruchter et al. (1999); only the last 5 ROTSE points are included. We have also adopted the time zero point for GRB 990123 from Fruchter et al. (1999). The data for GRB 021211 reported in the GCN Circulars are also plotted. We fit the same power-law model [eq. (1)] to the GRB 990123 data within 2 d after the burst and obtained the following parameters: $\alpha_1 = 1.80 \pm 0.11$, $\alpha_2 = 1.06 \pm 0.05$, and $t_b = 0.15 \pm 0.04$ hr (= 9.0 min). The reduced χ^2 of the fit is 1.10 for 20 degrees of freedom, which indicates eq. (1) is an adequate model to fit the data of GRB 990123. The fit parameters of GRB 990123 are very similar to those of GRB 021211, except for perhaps α_2, as the late-time decline of GRB 990123 is a bit steeper (as shown also by the residuals in the lower panel of Figure 3). Although the temporal evolution of both GRBs is consistent with a break at $t \approx 10$ min, the well-sampled KAIT data of GRB 021211 are the first to directly demonstrate the break and show a smooth transition between the two power-law decays.

Despite the overall similarity between the temporal evolution of the OA of the two bursts, GRB 990123 is brighter than GRB 021211 by about 3 mag at similar epochs, even though the former is probably at a larger redshift ($z = 1.600$; Hjorth et al. 1999). Other important differences between the two bursts are that (1) GRB 990123 is a much longer burst (lasting ~ 63.3 s; Galama et al. 1999) than GRB 021211 (lasting only ~ 2.5 s); (2) GRB 990123 is exceptionally bright in gamma rays, and has a fluence that is in the top 0.3% of BATSE bursts, while the gamma-ray fluence of GRB 021211 is in the middle of HETE-2 bursts reported by Barraud et al. (2003); and (3) the afterglow of GRB 990123

was successfully observed in optical, infrared, sub-mm, mm, and radio passbands, while the afterglow of GRB 021211 is detected only in the optical and infrared. In particular, a radio flare was observed for GRB 990123 (Kulkarni et al. 1999; Galama et al. 1999) and interpreted by Kulkarni et al. (1999) as evidence of reverse-shock emission. The apparent faintness of the OA of GRB 021211 compared with the OA of GRB 990123 suggests that the afterglow of GRB 021211 in other energy bands may be fainter as well, contributing to the reasons why it was not detected.

The current standard model for GRBs and their afterglows is the fireball shock model (for a review see Mészáros 2002). Based on this model, we expect a prompt multi-wavelength flash, contemporaneous with the gamma-ray emission and reaching V magnitudes ranging between 9 and 18 for typical GRB distances (Mészáros & Rees 1997; Sari & Piran 1999a; Sari & Piran 1999b). The prompt optical emission of GRB 990123 is not proportional to the gamma-ray flux, nor can it be understood as the low-energy extrapolation of the GRB spectrum (Galama et al. 1999). This indicates that the prompt optical emission and the GRB originate from different regions in the fireball. It has been popular practice to ascribe the origin of the GRB to the internal shocks (Rees & Mészáros 1994), and the long-term afterglow to the forward component of the external shocks. The prompt optical emission is explained as a consequence of the reverse component of the external shocks (Mészáros & Rees 1997; Sari & Piran 1999a). The decay rate of the optical flux from the reverse shocks is much faster than that of the forward shocks, so the emission of the latter dominates after tens of minutes. If this interpretation is correct, GRB 990123 and GRB 021211 would be the only two bursts in which all three emitting regions have been convincingly seen, and demonstrate that afterglow observations may give us insight into the geometry of the central engine of GRBs, as well as the structure of the relativistic ejecta.

The interpretation that the prompt and afterglow emissions come from different physical origins also implies that the two components are largely independent, so if both are declining as power laws, eq. (1) should be an adequate model to fit the data. The rather poor fit as discussed in §3 is thus surprising. Besides the possible explanation of a dramatic color change at early times (§3), another alternative is that there are small-scale variations in the reverse-shock emission superimposed on a power-law decline. It is also possible that the afterglow emission does not begin its power-law decay until after undergoing a brightening phase to a peak (e.g., Fox et al. 2003), in which case eq. (1) would not be an accurate model for the data. A full treatment of these possibilities is beyond the scope of the current *Letter*. We also emphasize that early-time photometry with high temporal resolution, preferably in multiple passbands, is necessary to determine which explanation is correct.

The small-scale variations in the reverse-shock emission, if real, are characterized by

a timescale of $\Delta t \approx t$. This suggests a process that involves the whole observable fireball surface. It will be difficult to achieve these variations in the reverse shock with external density inhomogeneities, and a refreshed shock (an extra energy input from the inner engine) seems to be a more promising explanation (e.g., Panaitescu, Mészáros, & Rees 1998). This would indicate a difference between the variability in GRB 021211 and GRB 021004, whose variability is believed to be caused by external density inhomogeneities (e.g., Lazzati et al. 2002).

The OA of GRB 021211 declined 4 mag in half an hour, and was fainter than 20 mag just over 2 hr after the burst. These observations may shed some light on the mystery of the so-called "dark bursts," in which no OA is seen (Fynbo et al. 2001; Berger et al. 2002). Explanations for the non-detections of OAs when deep, prompt searches exist are that they are (1) obscured by dust in their host galaxies, (2) at high redshifts, (3) intrinsically faint, and (4) fast decliners. Out of these, extinction by dust is often favored, since GRBs are suggested to be associated with massive star formation, and there are GRBs whose radio and infrared afterglows are detected but not the OA (e.g., GRB 980329; Yost et al. 2002). The relative faintness of the OA of GRB 021211 compared to the OA of GRB 990123, and its rapid optical decay, suggest that *some* dark bursts may be intrinsically dim, and not obscured by dust. The faintness of such OAs, coupled with the fast decline typical of OAs, will make them difficult to observe at high redshifts. Thus, the diversity in the underlying properties of OAs must be observationally determined before substantive inferences can be drawn from the statistics of dark bursts.

The KAIT observations of GRB 021211 demonstrate the importance of rapid turnaround in localizing GRB positions and intensive followup observations. Future prospects for optical observations of GRBs are bright: with continuing contributions from HETE-2, and the planned mission of Swift, fast and accurate GRB positions will be delivered automatically to the ground for rapid followup by KAIT and other robotic systems.

We thank S. Barthelmy for his help setting up the KAIT GRB alert system, and the referee for useful comments. The work of A.V.F.'s group at U. C. Berkeley is supported by NSF grant AST-9987438. KAIT was made possible by generous donations from Sun Microsystems, Inc., the Hewlett-Packard Company, AutoScope Corporation, Lick Observatory, the NSF, the University of California, and the Sylvia and Jim Katzman Foundation. S.J. thanks the Miller Institute for Basic Research in Science at U. C. Berkeley for support through a research fellowship.
